Sequence A: Base level of pit sequence of parallel-laminated muds and claystone with some interlaminae of silt; claystone is greenish gray to light gray, waxy, carbonaceous; at contact of sequences A and B pyrite nodules occur

Sequence B: Yellowish gray, slightly micaceous, parallel laminated mudstone with some interlaminae of silt and sand; ripples and desiccation cracks present; scattered ironstone nodules; rare root tracings

Sequence C: Crudely bedded, light gray, slightly micaceous siltstone with mudstone clasts

ABSTRACT

The uranium resource potential of the Palestine Quadrangle, Texas and Louisiana, was evaluated to a depth of 1500 in (5,000 ft) using criteria established for the National Uranium Resource Evaluation (NURE) program. Data derived from geochemical analyses of surface samples (substrate, soil, and stream sediment) in conjunction with hydrochemical data from water wells were used to evaluate geologic environments as being favorable or unfavorable for the occurrence of uranium deposits. The Palestine Quadrangle lies in the northeastern part of the Texas Gulf Coastal Province; structurally it is located within the southern part of the East Texas Embayment. Rock units, to depths less than 1500 m (5,000 ft), range in age from Early Cretaceous to Recent. Tertiary strata compose approximately 90 percent of the total surface area of the quadrangle. Cretaceous strata are restricted to the subsurface, except over shallow salt domes (Butler, Keechi, and Palestine), where undifferentiated Cretaceous sandstones, mudstones, and marls are exposed. Two favorable environments have been identified in the Palestine Quadrangle: (1) potential deposits of modified Texas roll-type in fluvial channels and associated facies within the Yegua Formation, and (2) potential occurrences along mineralization fronts associated with the Elkhart Graben and Mount Enterprise fault system. Unfavorable environments include: (1) Cretaceous shales and limestones, (2) Tertiary fine-grained marine sequences, (3) Tertiary sandstone units that exhibit favorable host-rock characteristics but fail to show significant syngenetic or epigenetic mineralization, and (4) Quaternary sands and gravels. Unevaluated units include the Woodbine Group (Upper Cretaceous), Jackson Group (Tertiary) and Catahoula Formation (Tertiary). The subsurface interval

St the Jackson Group and Catahoula Formation contains depositional facies that may opresent favorable environments; however, the evaluation of these units is inconclusive because of the general lack of shallow subsurface control and core material. The Woodbine Group, restricted to the subsurface except for a small exposure over Palestine Dome, occurs above 1500 m (5,000 ft) in the northwest quarter of the quadrangle. The unit exhibits favorable host-rock characteristics, but the paucity of gamma logs and cores as well as the lack of Hydrogeochemical and Stream-Sediment Reconnaissance (HSSR) data make evaluation of the unit difficult.

INTRODUCTION

PURPOSE AND SCOPE

The Palestine Quadrangle, Texas and Louisiana, was evaluated to identify geologic environments within mappable rock units and to delineate areas favorable for the occurrence of uranium deposits. The evaluation encompassed surface exposures and subsurface units to a depth of 1500 m (5,000 ft). Geologic environments are identified on the basis of their similarity to the classification of uranium deposits established by Mickle and Mathews (1978) and then categorized as favorable, unfavorable, or unevaluated.

Evaluation of the Palestine Quadrangle was conducted by the Bureau of Economic Geology under subcontract to Bendix Field Engineering Corporation for the National Uranium Resource Evaluation program managed by the Grand Junction Office of the U.S. Department of Energy. Work on Phase I was initiated April 1, 1978, and completed September 30, 1978; Phase II began October 1, 1978, and was completed March 31, 1980.

ACKNOWLEDGMENTS

Staff of the Bureau of Economic Geology who assisted in the field and on the preparation of the Palestine Quadrangle evaluation report include Keith Pollman, George Donaldson, Ben Herb, Linda Seekins, and Lee George. Dr. F. L. Brown was project coordinator, Doug Ratcliff and Dianne Sullivan were project managers, and Mark McClelland handled data processing. The ACME Brick Company was most

Ż

nerous in allowing us admittance to the Wilcox claypit near Garrison to collect ochemical samples; Mr. H. McQuay's assistance was appreciated. Varibus Corporaon (Beaumont, Texas) granted access to core on one of their lignite leases located on ail King's property south of Crockett, in Houston County; Mr. J. Musgrove and Mr. E. Heare of Varibus Corporation were most helpful in selecting a coring site. Permission to auger on road right-of-ways was granted by the Texas Department of Highways and Public Transportation. Mr. W. Goldsberry and staff of the Angélina County District Office assisted in selecting a site, in addition to providing traffic security for the augering operations. Debra Schiltz collected water samples from the Catahoula Formation, the data from which were used in the evaluation of the Palestine Quadrangle.

This research was funded by Bendix Field Engineering Corporation (subcontract 78-137-E) under prime contract to the U.S. Department of Energy (contract number DE-AC13-76GJO1664).

PROCEDURES

Data derived from geochemical analyses of surface samples (950 substrate, 404 soil, 120 stream sediment, and 51 water) in conjunction with the Hydrogeochemical and Stream-Sediment Reconnaissance Survey (Union Carbide, 1979) were used to evaluate geologic environments as being favorable for the occurrence of uranium deposits (PIs. 1, 4, 5 and 6). Plots of the ground-water geochemical analyses showed elevated uranium concentration values clustered in a few of the geologic formations, indicating areas favorable for uranium mobilization and mineralization in the Palestine Quadrangle (PI. 4). Similar plots of stream-sediment geochemical analyses produced a

random pattern of uniformly low uranium concentration values, and therefore did not indicate favorable areas (Indelicato, 1980). A preliminary aerial radiometric report for the Palestine Quadrangle (Texas Instruments, Incorporated, 1979) was available February 7, 1980. Time did not allow for detailed interpretation or field checking of radioactive anomalies; however, generalized conclusions derived from the report are included. Forty-nine anomalies were recorded, thirty-five of which were categorized as first priority. First-priority anomalies are defined as "those showing simultaneous statistically valid equivalent uranium, equivalent uranium/equivalent thorium, and equivalent potassium anomalies" (Texas Instruments, Incorporated, 1979).

Samples of rock, soil, stream sediment, and water were collected and submitted for geochemical analyses to the Mineral Studies Laboratory of the Bureau of Economic Geology under the supervision of Dr. Clara Ho (Pls. 5 and 6). Detailed geologic descriptions were made for each outcrop, including mineralogy, lithologies, and sedimentary structures. A Geometrics Model GR-101A portable scintillometer was used to measure gamma-ray counts for each sample and the background for each outcrop.

Subsurface data for Tertiary units in the Palestine Quadrangle were derived largely from earlier detailed studies of the Wilcox (Fisher and McGowen, 1967, 1969; Kaiser, 1974); Carrizo (Fisher, 1972); Queen City (Guevara and Garcia, 1972); Sparta, Cook Mountain (Ricoy, 1976); Yegua (Fisher, 1969; Kaiser and others, in press); Jackson (Fisher, and others, 1970; Kaiser, 1974) and the Catahoula (Galloway, 1977; Galloway and Kaiser, 1979). These investigations include regional cross sections, identification of principal depositional facies, and the construction of net sand or percent sand maps. Additional cross sections were constructed specifically for the Palestine Quadrangle (Pls. 10-16; Appendix D). These sections, in conjunction with data derived from off-section wells, were used to construct a structure map on top of the Wilcox Group (Pl. 18). The Hydrogeochemical and Stream-Sediment Reconnaissance Survey was used largely to identify environments favorable for uranium enrichment in the subsurface. Gamma-ray logs and cores are unavailable for most wells in this quadrangle.

A preliminary interpretation of the hydrogeochemical and stream-sediment data was performed by Bendix Field Engineering Corporation Data Integration Group and reported by Indelicato (1980). Methods used include frequency distributions and cumulative probability curves and the multivariant statistical techniques of principalcomponent analysis and correlation coefficients. The results were used in the final interpretation and integration of Hydrogeochemical and Stream-Sediment Reconnaissance data in the quadrangle evaluation.

Laboratory procedures used by the Bureau of Economic Geology Mineral Studies Lab in geochemical analyses of rocks, stream-sediment, and soil samples follow: (1) Rocks (2.5 kg) were first crushed and ground to less than 30-mesh size. A small portion (about 250 g) of the crushed sample was pulverized to less than 100-mesh for all subsequent chemical analyses. (2) Stream-sediment and soil samples were air-dried and pulverized slightly using a mortar and pestle. The less than 100-mesh fine fraction was separated by sieving through a polyethylene nylon sieve.

The following analytical procedures were used to determine total uranium concentrations:

(1) Total $U_{3}O_{8}$ in rocks -- Sample was fused with Li-tetraborate at 1050°C for 20 minutes. The flux was dissolved in 10 percent distilled HNO₃. An aliquot of the

plution was extracted with trioctylphosphine oxide (TOPO) dissolved in cyclohexane. Stal uranium was complexed by TOPO and partitioned into the cyclohexane layer. A mall aliquot of the latter was pipetted onto a NaF + KF (98:2) pellet. After fusing the pellet over a rotating multiple Fisher's burner, U_3O_8 fluorescence was measured on a Jarrell-Ash fluorometer (Ho and Dupre, 1980).

(2) Total U_3O_8 in stream sediments and soils -- Sample was digested with 50 percent distilled HNO₃ at 140°C on a Technicon BD-40 heating unit for 2 hours. The sample was then diluted with distilled water to make a final HNO₃ concentration of about 10 percent. U_3O_8 was then extracted in the same manner as that described for total U_3O_8 .

(3) Total U_3O_8 in water samples -- Appropriate amount of water was evaporated to a 5-ml volume in presence of 10 percent HNO₃. Total uranium was then extracted and measured in exactly the same manner as that described above (Ho and Dupre, 1980).

Multiple-element analyses were accomplished by Inductively Coupled Plasma Atomic Emission Spectrometer (ICP-AES). The instrument used in the Mineral Studies Laboratory (MSL) was the ARLQA-137 (Applied Research Laboratory) equipped with a minicomputer for data storage and processing. The instrument has the capability of analyzing 30 elements (Na, K, Mg, Ca, Al, Fe, Ti, Co, Cr, Cu, Mn, Ni, V, Zn, As, Cd, Mo, Pb, Sb, Se, Sn, Li, Be, Sr, Ba, Zr, U, Th, B, and P) simultaneously in less than 3 minutes' time per sample.

The sample was first digested with a mixture of concentrated $HNO_3 + H_2SO_4$ at 150°C followed by further dissolution with HCl. Supernatant was separated on centrifuge. The residue was decomposed with $HNO_3 + HF$ followed by dissolution with

a HNO₃ + HCI mixture. The supernatant and dissolved residue were combined and analyzed by ICP-AES.

GEOLOGIC SETTING

The Palestine 1° by 2° Quadrangle, an area of 20,000 km², is located between lat 31°00'00"N. and 32°00'00"N. and long 94°00'00"N. and 96°00'00"W. (Fig. 1). Physiographically the quadrangle lies within the northeastern part of the Texas Gulf Coastal Plain Province. Rock units to depths less than 1500 m (5,000 ft) range in age from Early Cretaceous to Recent (Fig. 2, Pl. 9).

Structurally, the Palestine Quadrangle lies within the southern part of the East Texas Embayment. The western and northern limits of the embayment are the Mexia-Talco fault system; the eastern boundary is the Sabine Uplift; and the southern margin is the Angelina-Caldwell Flexure (Fig. 3). There is a general basinward dip of sediments in the basin from the Mexia-Talco fault system on the north and west and from the Sabine Uplift on the east. Structural elements within the southern part of the embayment include the Elkhart Graben - Mount Enterprise fault system and salt domes restricted to the deeper, more central part of the embayment (Fig. 4).

The Elkhart Graben - Mount Enterprise fault system is a zone of complex faulting coincident with a hinge line that runs subparallel to and north of the Angelina-Caldwell Flexure (Nichols and others, 1968). This hinge line marks the southern limits of the East Texas salt dome province (Agagu and others, 1980a).

Gravity and seismic studies suggest that structures within the East Texas Basin are controlled by salt movement rather than major basement elements (Agagu and others, 1980a). Within the central parts of the basin, salt mobilization was initiated

with the first major influx of terrigenous clastics during the Late Jurassic-Early Cretaceous (Shuler and Travis Peak Formations). Salt was squeezed from areas of major sedimentation creating salt ridges in the intervening areas. Salt movement around the margins of the basin preceded Shuler - Travis Peak deposition (Agagu and others, 1980a). The initial salt ridges were the precursors of salt diapirs and associated faulting in the basin.

Approximately 10,000 m (33,400 ft) of Mesozoic and Cenozoic sediment have been penetrated in the central part of the East Texas Embayment (Agagu and others, 1980b). These deposits overlie metamorphosed Paleozoic sediments of the Ouachita system, which probably represents a continuation of the Appalachian foldbelt (Lyons, 1957; Wood and Walper, 1974; McGookey, 1975).

The Glen Rose Formation (Early Cretaceous) is the oldest unit to occur within 1500 m (5,000 ft) of the surface in the Palestine Quadrangle. The Early Cretaceous units underlying the quadrangle are composed of marine shales and carbonates (Granata, 1963; Fig. 2). Late Cretaceous sedimentation was initiated by an uplift of marginal areas of the East Texas Basin concomitant with Cenomanian lowering of sea level. The Woodbine Group, composed of sandstones and mudstones, marks the peak of clastic influx, and the Eagle Ford Formation, consisting predominantly of shales, marks the waning phase (Agagu and others, 1980b). Woodbine - Eagle Ford sedimentation was followed by a dominantly marine sequence composed of more than 1000 m (3,000 ft) of shelf muds and carbonates (Fig. 2). Minor influxes of terrigenous clastics are documented but are restricted to the northern part and flanks of the basin. The Tertiary deposits of the basin include a complex sequence of superposed fluvial, deltaic, marginal-strandplain (including lagoonal) deposits with minor occurrences of shelf deposits.

ENVIRONMENTS FAVORABLE FOR URANIUM DEPOSITS

Favorable environments in the Palestine Quadrangle include (1) potential deposits of modified Texas roll-type (Subclass 242, Austin and D'Andrea, 1978), epigenetic occurrences associated with local concentrations of carbonaceous debris in crevassesplay deposits coincident with an alteration front (Galloway, 1977, and Galloway and Kaiser, 1979), and (2) occurrences along mineralization fronts associated with faulting (Subclass 242, Austin and D'Andrea, 1978) (Pl. 1).

FAVORABLE AREA A -- YEGUA FORMATION

The subsurface interval of the Yegua Formation is considered a favorable area because characteristics of the fluvio-deltaic complex fulfill criteria established for Sandstone Subclass 242 -- Texas roll-type deposits (Austin and D'Andrea, 1978).

Surface exposures of the Yegua Formation include only the updip fluvial elements of the deltaic complex. The facies continues into the shallow subsurface and is composed of channel-fill sands and mud-rich interfluvial basin deposits. Diporiented sands form belts, 48 km (30 mi) wide and over 60 m (200 ft) thick (Fisher and others, 1970), which provide excellent conduits for ground-water flow (PI. 17). The Yegua fluvial sequence grades downdip into a delta-plain complex composed of elongate, distributary channel-fill sands, interdistributary muds, and abundant plant debris and lignite. Thin beds of volcanic ash are reported in some areas (Sellards and others, 1932). Cross sections B-B' and F-F' (PIs. 12 and 16) show the subsurface delta-plain sequence of interbedded sands and muds and thicker distributary sand channels. The Yegua Formation extends from the surface to a depth of 475 m (1,568 ft) in the southern part of the quadrangle and attains a maximum thickness of 364 m (1,200 ft).

The presence of uranium enrichment within the Yegua is suggested by geochemical data from surface samples of the unit in conjunction with preliminary data from the aerial radiometric survey, which delineates nine first-priority anomalies associated with the Yegua Formation (Fig. 5). Total uranium concentrations in channel sands in outcrop are characteristically low; however, overbank muds and interdistributary deposits show higher concentrations, generally coincident with carbonized plant debris and lignites. Maximum concentrations of U_3O_8 are 52.5 ppm in carbonaceous overbank muds of the Yegua Formation (Fig. 5). The presence of U_3O_8 , in the above concentrations, in mud-rich sequences probably suggests that syngenetic mineralization occurred within these facies. The extremely low levels of U_3O_8 associated with sands suggest that any available uranium resulting from diagenesis and alteration of volcanic ash was leached and mobilized downdip by ground-water flow systems. Oxidizing ground waters coming in contact with reducing environments of organic-rich, crevasse-splay sands could produce mineralization fronts resulting in deposition of uranium. Concentrations of carbonized plant debris and lignite would serve as reductants. Crevasse splays interfinger with highly carbonaceous and lignitic muds that provide permeability barriers and geochemical gradients favorable for precipitation of uranium. The model for this kind of uranium mineralization is described by Galloway and Kaiser (1979) for a Catahoula uranium deposit in Fayette-Washington Counties (Fig. 6). The deposit occurs along an alteration front within a crevasse-splay sand body downdip from a fluvial channel. Uranium mineralization of ore grade appears to occur in pods along an alteration front in areas adjacent to high concentrations of organic material. The deposit is compared to "trash pile" accumulations of the Colorado Plateau; however, in this case, the deposit is coincident with a well-defined mineralization front.

Of a total of 155 ground-water samples collected from the Yegua Formation, 15 samples contain uranium concentrations greater than the 0.44 ppb mean. These samples also have higher than average uranium-conductivity ratio values. The elevated geochemical values are clustered in three anomalous areas (Pl. 4) that delineate possible uranium occurrences.

The first area is located in eastern Houston County (Pl. 4) and contains five samples ranging in concentration from > 1.70 to > 20 but < 50 ppb. The depth of the producing horizons ranges from 4 m (13 ft) to 74 m (244 ft), with deeper wells containing the lower geochemical values. The second anomalous area, in southeastern Houston and northwestern Trinity Counties, contains five samples from the Yegua Formation, ranging in uranium concentration from > 0.50 to > 6 but < 10 ppb. The depth range for these samples is 8 m (26 ft) to 77 m (254 ft), with higher geochemical values occurring predominantly in the shallower wells. The third area is a cluster of four samples in central Angelina County that range in uranium concentration from > 0.80 to > 3.50 but < 6.00 ppb. Samples from this area range in depth from 6 in (20 ft) to 31 in (102 ft); however, there does not appear to be a correlation between depth and geochemical values. All three anomalous areas have moderate uranium/conductivity ratios, which suggest that the samples are slightly saline in character. The elevated uranium concentrations are believed to be a function of an increase in the total dissolved solids content (Indelicato, 1980). However, tuffaceous material is indigenous to the Yegua Formation, and where favorable geohydrologic environments exist, minor accumulations of uranium may occur. Downdip of the anomalous areas, the uranium concentrations and the uranium/conductivity ratios are observed to diminish. Here, the uranium concentration in the ground water appears to be inversely related to the total

dissolved solids content. It should be noted that as the salinity of ground water increases, the concentration of ionic species capable of interfering with uranium analyses also increases. Thus uranium concentration values and uranium/conductivity values of brines are not reliable. However, available Texas Department of Water Resources data (Peckham and others, 1963; Tarver, 1966, 1968; Anders, 1967; and Guyton and Associates, 1970) indicate that the ground water of the Yegua Formation is fresh to slightly saline in the outcrop area and a few miles in the downdip direction. In areas directly downdip of the anomalies, uranium could be precipitating in suitable geologic environments rather than being flushed downdip into the brines. Onlap of tuffaceous deposits of the Jackson Group and Catahoula Formation over the Yegua Formation may have served as a source for downward-percolating, enriched ground waters.

A core 10.3 m (34 ft) in length was taken from the Yegua Formation in Houston County (Fig. 5). The core penetrated a sequence of interchannel laminated muds and silts with thin interbeds of sand. One lignite bed approximately 2 m (6 ft) thick was encountered. The core was sampled selectively to determine total uranium, particularly in the lignite and highly carbonaceous units. Concentrations ranged from 1.5 to 9.8 ppm. Total uranium in the carbonaceous zones and lignite bed ranged from 4.3 to 7.3 ppm, respectively. The interface between the lignite and overlying unconsolidated sand unit was not sampled because the material was lost in coring. The highest concentration (9.8 ppm) occurred in a burrowed sequence of interlaminated mudstone and siltstone at a depth of approximately 10 m (33.3 ft). The uppermost 60 cm (2 ft) of core penetrated the B and C soil horizons. The A horizon, a very loses sand, could not be recovered. Total U₃O₈ concentrations in the soil range from 4.5 to 6.3 ppm.

The highest concentration occurred at a depth of approximately 43 cm (1.5 ft) in the C or bedrock horizon. The median concentration occurred in an oxidized ironstone horizon at a depth of approximately 20 cm (0.7 ft).

Approximately one half of the Palestine Quadrangle overlying the subsurface Yegua Formation section is privately owned. The remaining half falls within the Davy Crockett and Angelina National Forests. For exact boundaries, refer to Plate 21.

FAVORABLE AREA B -- ELKHART GRABEN - MOUNT ENTERPRISE FAULT SYSTEM

The Elkhart Graben - Mount Enterprise fault system is considered a favorable area for uranium enrichment because characteristics of the system and faulted rock units within the subsurface fulfill criteria established for Subclass 242 -- Texas rolltype deposits (Austin and D'Andrea, 1978). The preliminary aerial radiometric report for the Palestine Quadrangle (Texas Instruments, Incorporated, 1979) indicated five first-priority anomalies aligned northeast-southwest along the Elkhart Graben and four first-priority anomalies showing a similar alignment, along the Mount Enterprise fault system in the northeastern part of the quadrangle (Fig. 7).

Evidence of uranium mineralization related to faulting in the Palestine Quadrangle is suggested from geochemical analyses of rock samples collected from the Queen City Formation 10 km (6 mi) south of Jacksonville, Cherokee County, on Highway 69. Laminated, highly glauconitic mudstones of the Weches Formation are faulted against interlaminated mudstones and siltstones and thinly-bedded, crossstratified sands of the Queen City Formation. Uranium concentrations attain a maximum value of II.8 ppm within thin-bedded, cross-stratified sands found in

approximately the lower 2 m (6 ft) of the outcrop. Concentrations decrease rapidly upward in the interlaminated mudstones and siltstones and average 3 ppm. Scintillometer counts also increase from 52 counts per second to 120 counts per second within the lower sands, but decrease rapidly to background levels in areas away from the fault zone. Typical low U_3O_8 concentrations in substrate samples collected from the Queen City Formation at other sample locations suggest that the low-level enrichment recorded south of Jacksonville is structurally rather than facies related. More significant concentrations may occur within the subsurface coincident with the fault.

Faults can produce vertical flow paths that cross less permeable facies and allow upward migration of uranium enriched fluids or extrinsic reductants in the form of sulfide rich fluids or H_2S gas associated with hydrocarbon accumulations. Examples of uranium deposits coincident with faulting occur in the Catahoula Formation (Galloway, 1977) and Jackson Group (Fisher and others, 1970) in South Texas.

All of the land overlying the subsurface section of the Elkhart Graben - Mount Enterprise fault system is privately owned.

The Elkhart Graben - Mount Enterprise fault system (Figs. 4 and 7) and other structural features such as salt domes have not been adequately evaluated in the Palestine Quadrangle as potential areas for uranium mineralization, especially in the subsurface. Surface exposures are generally limited and of poor quality, and gammaray well logs are not readily available to aid in recognizing radioactive anomalies within the subsurface. A reconnaissance survey of the fault zone and Keechi, Palestine, and Butler salt domes yielded scintillation counts of 20 to 40 counts per second with no significant increases near structural features.

ENVIRONMENTS UNFAVORABLE FOR URANIUM DEPOSITS

Unfavorable environments within the Palestine Quadrangle include (1) Cretaceous shales and limestones (Classes 130 and 230, Jones, 1978); (2) Tertiary fine-grained marine deposits (Class 130, Jones, 1978); (3) Tertiary sandstone units that exhibit favorable host-rock characteristics but fail to show significant syngenetic or epigenetic uranium mineralization; and (4) sands and gravels of Quaternary age.

CRETACEOUS SHALES AND LIMESTONES

Lower and Upper Cretaceous marine shales and carbonates (Fig. 2) are restricted to the subsurface, except over Keechi, Butler, and Palestine salt domes, where undifferentiated Cretaceous sandstones, mudstones, and marls have been mapped (Powers, 1920; Lahee, 1933; Hightower, 1958; Ebanks, 1965; Barnes, 1967). In the subsurface, Cretaceous units occur above 1500 m (5,000 ft) in the northern half of the quadrangle and on the southwestern flank of the Sabine Uplift (Pls. II and 15). Marine shales (Class 130, Jones, 1978) probably experienced some syngenetic mineralization; however, occurrences of this type would represent very low grade resources. The depth of occurrence in the subsurface would eliminate these units from further consideration. Cretaceous limestones (Class 230, Jones, 1978) represent environments that were not conducive to uranium mineralization.

TERTIARY DEPOSITS

Unfavorable environments of Tertiary age include fine-grained marine deposits of the Claiborne Group (Reklaw Formation, Weches Formation, and Cook Mountain Formation) and fluvial-deltaic sequences that exhibit excellent host-rock character-

istics but fail to show significant syngenetic or epigenetic uranium enrichment (Carrizo Formation - Wilcox Group, Queen City Formation, and Sparta Sand) (Fig. 2).

Marine sequences of the Claiborne Group are dominated by fine-grained shelf deposits composed of glauconitic mudstones exhibiting abundant whole and fragmented shell material. Geochemical data show no evidence of uranium mineralization in these geologic units. An aerial radiometric anomaly was reported in the Weches Formation just north of San Augustine (Atomic Energy Commission, Preliminary Reconnaissance Report, File No. 2487) (Pl. 2). The area was relocated in the field and sampled extensively. Scintillometer readings are slightly elevated above background; however, U_3O_8 concentrations ranged from 2.5 to 4.4 ppm. The anomaly may be related to the presence of locally occurring ironstone ledges within the Weches Formation.

Those geologic units exhibiting favorable host-rock characteristics but no significant uranium enrichment include the fluvial-deltaic complexes of the Carrizo Formation - Wilcox Group, Queen City Formation, and Sparta Sand (Figs. 8, 9, and 10). Component facies of these units have been described and mapped by Fisher and McGowen (1967, 1969), Fisher (1972), Guevara and Garcia (1972), and Ricoy (1976). Depositional facies include fluvial and distributary channel sands, crevasse splays, and highly organic interdistributary muds and lignites--all analogous to environments considered favorable in the Yegua Formation. Wilbert and Templain (1978) conducted a preliminary regional evaluation of uranium favorability of the Wilcox and Claiborne Groups in Texas and concluded that no mineralization had occurred.

Criteria used to determine unfavorability of geologic environments in this study relied heavily upon hydrogeochemical data from the Hydrogeochemical and Stream-Sediment Reconnaissance Survey. The multivariant statistical analysis performed by

the Bendix Field Engineering Corporation Data Integration Group delineates potentially favorable areas on the basis of elevated, clustered uranium concentrations and uranium conductivity values of stream-sediment and ground-water samples (Indelicato, 1980). There are no elevated, clustered values for the Carrizo Formation - Wilcox Group, Queen City Formation, or Sparta Sand. Most values for these geologic units are < 0.30 ppb uranium. However, there are two isolated ground-water samples collected in the area of the Wilcox Group outcrop that contain uranium concentrations of > 10 but < 20 ppb and > 3.5 but < 6.0 ppb. The values are at least a magnitude greater than those values calculated for samples from water wells in the vicinity.

Geochemical analyses of substrate samples indicate low uranium concentrations associated with surface exposures of the Carrizo Formation – Wilcox Group, Queen City Formation, and Sparta Sand. The absence of intrinsic volcanic detritus was probably the main factor contributing to the absence of uranium enrichment in these units. However, volcanic-rich clastics of the Yegua Formation, Jackson Group, and Catahoula Formation probably overlapped the Wilcox and Claiborne Groups prior to Pleistocene time, thus providing a source for epigenetic mineralization by uranium enriched ground waters. The efficiency of this proposed enrichment process would have been hindered by a humid paleoclimate (Fisher and others, 1970; Galloway, 1977). Studies of Modern shallow aquifers in Jasper and Newton Counties indicate that approximately one-third to one-half of the potential recharge is rejected (Wesselman, 1967). Dilution of the uranium cycle by recharge rejection concomitant with continued flushing would have placed extreme limitations on the potential for epigenetic enrichment. In addition, erosion of the Yegua, Jackson, and Catahoula deposits during Pleistocene sea-level changes removed these possible sources for uranium.

QUATERNARY DEPOSITS

Sands and gravels associated with Recent alluvial and Pleistocene terrace deposits show little potential for uranium enrichment. Stream-sediment analyses from the Hydrogeochemical and Stream-Sediment Reconnaissance Survey and this study indicate low uranium concentration values that range from 0.0 to 4.10 ppm.

UNEVALUATED ENVIRÓNMENTS

Unevaluated units of the Palestine Quadrangle include the Woodbine Group (Upper Cretaceous), Jackson Group (Tertiary), and Catahoula Formation (Tertiary) (Fig. 2). The subsurface interval of the Jackson Group and Catahoula Formation contains depositional environments that exhibit characteristics favorable for uranium enrichment; however, the evaluation of these units is inconclusive because of the general lack of shallow subsurface control and core material.

WOODBINE GROUP

The Woodbine Group has the greatest uranium resource potential of all the Upper Cretaceous units; however, it remains largely unevaluated. The formation is restricted to the subsurface except for a small exposure over Palestine Dome (Hightower, 1958) (Pl. 19). It occurs above 1500 m (5,000 ft) in the northwest quarter of the quadrangle, attains a maximum thickness in the north in synclinal areas adjacent to salt domes, and is thinnest at the pinch-out in the east along the Sabine Uplift. There is no hydrogeochemical data available for the Woodbine Group.

Four criteria favorable for uranium mineralization are present in the Woodbine Group:

(1) An indigenous uranium source, provided by an extensive volcanic ash deposit, exists in the Woodbine (Ross and others, 1928).

(2) A geologic framework providing suitable component facies and lithologies is present within the Woodbine. According to Oliver (1971), the Woodbine Group in the study area is dominated by the coastal-barrier and channel-mouth-bar facies of the high-destructive Freestone Delta System. [Descriptions of representative facies are based on surface exposures and well cuttings (Oliver, 1971).] The coastal-barrier facies strikes east-west and is composed largely of well sorted sands interbedded with dark gray to brown shales with some sands containing marine fossils, glauconite, and finely divided carbonaceous materials. Landward, coastal-barrier sands are interbedded with lagoonal or marsh-type muds; offshore they grade into shelf- and prodelta muds. Areas of maximum sand thickness are perpendicular to major fluvial axes and exhibit well-sorted, low-angle crossbeds, parallel beds, ripple cross-stratification, and horizontal laminations. Channel-mouth-bar facies are limited to an area underlying northeast Anderson County. The sand of this facies is commonly finer than fluvial sands, is well sorted and exhibits ripple marks and scattered glauconitic, carbonaceous and fossil material. The sands of the channel-mouth-bar facies are laterally transitional, with flanking coastal-barrier sands. Thus, the sands of these facies provide a fairly continuous, permeable environment favorable for oxidation, leaching, and transportation of uranium during depositional and early postdepositional times.

(3) A hydrologic flow system and possible favorable geochemical conditions exist in the Woodbine Group. The ground water is confined and under great artesian

pressure. Discharge occurs by the process of upward leakage through confining beds (Peckham, 1963) and fault planes. The ground water is considered to be too mineralized to be useful and no water wells in the Palestine Quadrangle tap Cretaceous water (Guyton and Associates, 1972). Brooks (1960) suggests that compaction of sediments in the East Texas Basin has forced chemically reducing waters from underlying shales through the Woodbine Group. If this is the case, then these waters may have enhanced the mineralization activity of indigenous reducing waters and introduced a reducing environment in previously oxidized areas of the Woodbine sands.

(4) Faults and salt domes cause interruptions and alternating thinning and thickening of Woodbine sediments, creating traps in some areas and conduits in others for ground-water and hydrocarbon movement. The Woodbine Group in the study area is faulted by the Mount Enterprise system and Elkhart Graben -- both areas associated with known hydrocarbon production. Possible occurrences of uranium mineralization may exist wherever the Woodbine overlies or pinches out against salt domes. Known hydrocarbon production occurs in the Woodbine in the vicinity of Brushy Creek, Boggy Creek, and Butler Domes (Pl. 18), where upward migration of H_2S and other reductants could create a favorable environment for mineralization. Such an occurrence is found in the Goliad Sand overlying Palangana Dome of South Texas (The Southern Interstate Nuclear Board, 1969).

JACKSON GROUP

The Jackson Group in East Texas is part of the larger Fayette fluvial-deltaic system described by Fisher and others (1970). East of the Angelina River, the fluvialdeltaic system grades laterally into the Yazoo - Moodys Branch shelf system.

Within the outcrop belt of the Jackson Group, all four (fluvial, delta-plain, deltafront and prodelta) facies of the fluvial-deltaic complex are recognized (Fisher and others, 1970) (Fig. 12). The component facies of the system are approximately coextensive with the four formations of the group: the Whitsett represents the fluvial facies, the Manning represents delta-plain deposits, the Wellborn represents deltafront sequence, and the Caddell represents prodelta muds (Fisher and others, 1970). The Jackson Group ranges in thickness from around 121 to 273 m (400 to 900 ft), attaining maximum thickness in the subsurface.

The fluvial facies is composed of channel-fill sands and interchannel muds. Sands are generally tuffaceous, fine- to medium-grained, and contain lignitic fragments, silicified wood, and angular mud clasts. Typical sedimentary structures include several cross-stratification types: moderate- to large-scale trough and foreset crossbeds, small- to moderate-scale tabular crossbeds, and current-rippled cross-laminae. Interchannel overbank muds are generally gray to dark brown and carbonaceous or lignitic. Altered ash beds occur locally. Dominant sand axes are dip-oriented as illustrated in Figure 11.

Delta-plain deposits of the Jackson Group (Manning Formation) are composed of alternating sands, muds, and lignites. Distributary-channel sands are generally finegrained and trough cross-stratified. Interdistributary muds are laminated to thinbedded and carbonaceous. Discontinuous, tabular lignite beds are characteristic of this facies. Crevasse-splay deposits and levee deposits are commonly associated with distributary channel-fill sequences.

The delta-front facies generally represents the Wellborn Formation and consists of two types of sand units: thick-bedded cross-stratified sands and thin-bedded flaggy sands. Fisher and others (1970) interpret the thicker sands to be dominantly shoalwater, channel-mouth bars and the thinner sands to represent the more distal margins of the delta-front sequence. Updip this facies grades into delta-plain deposits and downdip, into marine muds.

The fourth component facies -- prodelta and shelf muds -- comprises the Caddell Formation. This facies consists of thick sequences of dark, laminated glauconitic mudstones. The mudstones contain finely disseminated organic material, shell material, and foraminifers.

East of the Angelina River the fluvial-deltaic system of the Jackson Group grades laterally into the Yazoo - Moodys Branch shelf system, represented by a sequence of predominantly marine muds. Only a small area of this system is located within the Palestine Quadrangle.

Geochemical analyses of rock samples from the Jackson Group indicate that uranium enrichment has occurred within the unit. In general, total uranium concentrations are low in channel sands but show higher concentrations in organic-rich overbank muds and interdistributary deposits (Fig. 12). Maximum concentrations (37.5 ppm) of U_3O_8 occur within the delta-plain facies (Manning Formation) of the Jackson Group. Characteristically low total U_3O_8 concentrations associated with channel sands suggest that any available uranium resulting from argillation of volcanic ash was leached by ground water and migrated downdip by ground-water flow systems. Oxidizing ground waters within the main fluvial channels coming in contact with reducing environments of organic-rich, crevasse-splay sands, could produce mineralization fronts resulting in deposition of uranium. The subsurface interval of the Jackson Group in the Palestine Quadrangle is largely unevaluated because of a lack of shallow subsurface data.

CATAHOULA FORMATION

The Catahoula Formation of northeast Texas is part of the Chita-Corrigan fluvial system as defined by Galloway (1977) and Galloway and Kaiser (1979) in their detailed regional studies of the formation. Galloway (1977) and Galloway and Kaiser (1979) compare and contrast this system to the Gueydan fluvial system of South Texas where uranium production occurs. The system is composed of stacked channel-fill sequences and associated crevasse-splay sands alternating with mud-rich facies of well-drained floodplain muds and silts and interchannel lacustrine muds, clays, and sands. Altered volcanic ash is a dominant component of crevasse-splay and interchannel facies. The formation outcrops in the southeastern part of the quadrangle and ranges in thickness from 91 to 183 m (300 to 600 ft) (Fig. 13). The beds thicken and dip basinward at less than 1° and grade downdip into an equivalent wave-modified, lobate-delta system of the Frio Formation.

Channel-fill sequences in the easternmost part of the Chita-Corrigan system tend to spread out laterally rather than stack vertically as in the central and western part of the system. Thus interchannel mudstones and claystones become a more important facies. Net sand maps of the Upper Catahoula and Lower Catahoula intervals demonstrate this relationship (Figs. 14 and 15) (Galloway, 1977).

The change in sand distribution pattern has an important influence on the ground-water flow system. The more permeable channel-fill sands of the Lower Catahoula, which are laterally separated by the less permeable interchannel mudstones and claystones, behave as conduits for ground-water flow. In the central and western part of the Chita-Corrigan system, the vertical stacking of channel-fill sands creates the hydrologic continuity between Upper and Lower Catahoula, which allows upward

discharge of ground water as well as enhancing influx from the updip recharge area. In he easternmost area of the system, the overlying laterally continuous claystone and mudstone interchannel deposits are effectively an aquitard capping the Lower Catahoula sands. The aquitard restricts the upward discharge of ground water and likewise the downward percolation of ground-water recharge. The outcrop exposure of the aquitard reduces the surface area of the recharge zone, thus reducing the volume of ground-water influx.

Dominant framework facies include channel-fill sands and crevasse-splay deposits. Channel-fill sequences are generally composed of moderately to well sorted, very fine to medium sand with local lenses of mudstone and muddy sandstone. Mud clast conglomerates are common as channel-lag deposits; clay pellets and chips are common in the upper part of the sequence. Ferruginous nodules and fragments of silicified wood are common. Sedimentary structures include medium- to large-scaled, low- to high-angle trough cross-stratification and scour features. Planar beds and foreset crossbeds are common locally. Occurrence of ripples, mud drapes, and root structures is also noted. Channel-fill units average 11 to 14 m (35 to 45 ft) in thickness.

Crevasse-splay sequences, commonly associated with channel-fill deposits, are characterized by a variety of bedding structures and textures. Sequences of laminated to thickly and poorly bedded sands and sandstones, muddy sands, siltstones, and mudstones typically compose crevasse-splay deposits. Ripples, climbing ripples, mud drapes, desiccation cracks, rooted zones, and dewatering structures are common; sands are locally cross-stratified. Ironstone nodules, carbonized or siliceous wood fragments, and local concentrations of plant debris are common accessory features. Vuggy textures are commonly associated with mudstone units.

Crevasse-splay deposits interfinger laterally with floodplain and lacustrine nudstones and siltstones. Deposits typically form coalescing aprons that thin away from the channel axes. Crevasse-splay sequences are commonly 10 km (63 mi) wide and reach a maximum thickness of 9 m (30 ft).

Interchannel lacustrine deposits represent the major nonframework facies in the Palestine Quadrangle; floodplain deposits are a minor facies. Lacustrine basin deposits are typically massive, olive to gray, bentonitic claystones that grade vertically upward and laterally into beds of tuffaceous muds, silts, and fine sands. Organic material in the form of disseminated plant debris and large wood fragments is common to abundant. Silts and fine sands are typically laminated, with climbing ripple cross-lamination and medium- to small-scale trough cross-stratification occurring locally. Burrowed zones, root casts, clay drapes, dewatering structures, and desiccation cracks are common. Galloway (1977) describes the following typical progradational sequence for the lacustrine facies: (1) massive homogenous claystone, (2) massive to poorly bedded mudstone containing root traces and burrows, and (3) thick- to medium-bedded, highly root-disturbed silty mudstone to muddy sandstone. Lacustrine deposits are commonly tens of meters thick and stacked sequences may be several hundreds of meters thick. Lateral dimensions are variable.

Well-drained floodplain sequences are not as well developed in the eastern part of the Chita-Corrigan system as they are to the west. Deposits are generally tuffaceous mud, silt, and clay. Common accessory features include ironstone and calcareous nodules with local occurrences of gypsum veins. Rooted zones and vuggy textures are commonly associated with the mudstones.

Sands of the Catahoula consist of quartz with subequal amounts of orthoclase, lagioclase, and rock fragments (Galloway, 1977). Kaolinite is the dominant clay nineral in interchannel floodbasin and lacustrine mudstones and claystones. The absence of detrital illite, chlorite, or their mixed layer variants suggests that the clays are primarily derived from altered airborne volcanic ash rather than from older rock units. On the basis of gross mineralogy, Galloway (1977) suggests that from 70 to 90 percent of the clay in the Chita-Corrigan system was derived from volcanic ash. Volcanic detrital material served as the source of uranium released into the system during argillation of the ash. Total U_3O_8 concentrations associated with highly carbonaceous lacustrine basin clays are probably syngenetic in origin. Available uranium, released during early diagenesis, was probably adsorbed by finely disseminated carbonaceous plant debris in the lake basins.

Hydrogeochemical and stream-sediment reconnaissance data are available only for that portion of the Catahoula that lies within the Palestine Quadrangle. A total of 12 ground-water samples were collected and analyzed. The uranium concentration values are generally very low, ranging from 0.0 to 0.50 ppb, with an average value of 0.14 ppb. The depth range of the producing horizons was 6 to 123 m (18 to 369 ft), with six of the wells producing from horizons less than 9 m (30 ft) in depth. Plots of the uranium and trace element concentrations and uranium/conductivity ratios indicate there is little uranium in the ground water. Low uranium concentrations in surface sand deposits and ground-water samples suggest that most of the uranium once present in these more permeable deposits has been leached and mobilized. Favorable environments for the precipitation of uranium in the shallow subsurface of the Catahoula may exist downdip in the region covered by the Beaumont Quadrangle.

The following two environments are categorized as favorable for potential ranium mineralization within the Catahoula Formation; however, both are uneval-

(1) Potential deposits of modified Texas roll-type (Subclass 242, Austin and D'Andrea, 1978), restricted to the subsurface of the Catahoula Formation -- The model is based on a uranium deposit in the Chita-Corrigan fluvial system in Fayette-Washington Counties described by Galloway and Kaiser (1979) (Fig. 6). Uranium occurs along an alteration front within a crevasse-splay sand body that lies downdip from a fluvial channel. Uranium mineralization of ore grade appears to occur in pods along an alteration front related to areas of high organic concentration.

(2) Unclassified lacustrine basin syngenetic deposits containing anomalous total uranium concentrations -- An example of this type of occurrence is located in a road material pit located approximately one-half mile east of the town of Browndell (Fig. 13). This location is east of the Palestine-Alexandria Quadrangle boundaries; however, it is included in this report because analogous occurrences are likely to be present in the shallow subsurface of the Palestine Quadrangle. This Catahoula depositional sequence can be subdivided into three units (Fig. 16). Anomalous occurrences of U_3O_8 , indicated by geochemical analysis of substrate samples, is associated with sequence A, a sequence of greenish gray to light gray, parallel-laminated, waxy claystones with minor amounts of silt. Finely disseminated plant debris is common. These claystones are interpreted to be lacustrine basin deposits and are overlain by sequence B, consisting of yellowish gray, slightly micaceous, parallel-laminated mudstones and siltstones. The presence of root tracings, ripples, and desiccation cracks suggests that this sequence was deposited in a lacustrine-margin environment that was subject to

periods of subaerial exposure. Sequence B is overlain by poorly bedded siltstone with common mudstone clasts scattered throughout the interval. The level of U_3O_8 decreases markedly upward through the overlying lake-margin muds and silts (Fig. 16). The base level of the pit bottoms in the lacustrine clays; thus the thickness of sequence A is unknown. Galloway (1977) reports that lacustrine deposits in the Chita-Corrigan system are of variable width and typically tens of meters or feet thick.

Within the same area, in an adjoining abandoned pit east of sample number MGR-012, a sample was taken from a partially silicified log. Geochemical analyses indicate a U_3O_8 level of 45 ppm; concentrations in the surrounding mudstones and siltstones are appreciably lower. Galloway (1977) also reports U_3O_8 levels of 41 ppm and 36 ppm in lacustrine deposits sampled in Jasper (same area as sample MGR-012) and Walker Counties, respectively.

A uranium deposit of ore grade associated with Miocene lacustrine deposits in western Arizona is described by Sherborne and others (1979). Sherborne and others suggest that uranium-bearing fluids expelled during subsequent compaction of these sediments came in contact with a strongly reducing environment causing precipitation and fixation of uranium. Concentrations of U_3O_8 range from 0.03 to 0.10 percent, with an average of 0.07 percent.

Based on detailed regional studies, Galloway (1977; Fig. 31) speculates that uranium deposits that may occur in the Catahoula Formation in East Texas will range from small (10^5 lbs U_3O_8) to medium (10^6 lbs U_3O_8). These figures are based on size categories established for uranium deposits in the Catahoula of South Texas.

Approximately two-thirds of the Catahoula Formation subsurface section underlies the Angelina National Forest (Pl. 21). The remaining third is privately owned.

RECOMMENDATIONS TO IMPROVE EVALUATION

Potential favorable environments on the Palestine Quadrangle are restricted to the subsurface (Yegua Formation, Jackson Group, Catahoula Formation, and the Elkhart Graben – Mount Enterprise fault system). Thus the evaluation of the quadrangle would be greatly enhanced through a selective coring program. Three drilling programs are suggested:

(1) A coring program of the lacustrine basin deposits in Jasper County (Catahoula Formation) (Fig. 13), which contain anomalous occurrences of total uranium, would determine the lateral and vertical extent of the sequence. Analogous deposits should occur within the subsurface section of the Catahoula Formation underlying the Palestine Quadrangle. Knowledge of the size of lacustrine basin deposits would aid in evaluating their importance as a potential favorable environment for low-grade uranium deposits.

(2) Kaiser and others' (in press) sand percent map (Pl. 17) of the Yegua Formation, which shows the distribution of major channel sands, could be used as a model for coring marginal areas of the high sand trends to locate genetically associated crevasse-splay deposits, which represent an environment favorable for uranium mineralization.

(3) A paucity of shallow subsurface data within the fluvial facies of the Jackson Group on the Palestine Quadrangle would make an analagous coring program for this group more difficult.

(4) A coring program along the Elkhart Graben - Mount Enterprise fault trend, particularly in those areas where first-priority radioactive anomalies occur, would aid

in evaluating the possibility of uranium deposits coincident with faulting in the quadrangle.

In conclusion, a more complete evaluation of favorable environments within the Yegua Formation, Jackson Group, and Catahoula Formation could be made by the collaboration of data from the Palestine and adjoining Beaumont Quadrangle to the south. The Beaumont Quadrangle is currently being evaluated by Bendix Field Engineering Corporation, Austin office.

Cross-referencing ground-water wells sampled for the Hydrogeochemical and Stream-Sediment Reconnaissance Survey with those ground-water wells on file at the Texas Department of Water Resources would improve the interpretation of geochemical data and thus the evaluation of the Palestine Quadrangle.

Additional, pertinent data are available for many of the Hydrogeochemical and Stream-Sediment Reconnaissance wells and have been published in county groundwater resources reports by the Texas Department of Water Resources. There are six such reports covering eleven counties in the Palestine Quadrangle. Also it would be helpful for the National Uranium Resource Evaluation project researchers if hydrogeochemical and stream-sediment data contained standard definitions of fresh, brackish, and saline water.
